12 Q17

Intergenerational Transmission of Maternal Childhood Maltreatment Prior to Birth: Effects on Human Fetal Amygdala Functional Connectivity

Marion I. van den Heuvel, PhD[®], Catherine Monk, PhD[®], Cassandra L. Hendrix, PhD[®], Jasmine Hect, MSc[®], Seonjoo Lee, PhD[®], Tianshu Feng, MS, Moriah E. Thomason, PhD[®]

Objective: Childhood maltreatment (CM) is a potent risk factor for developing psychopathology later in life. Accumulating research suggests that the influence is not limited to the exposed individual but may also be transmitted across generations. In this study, we examine the effect of CM in pregnant women on fetal amygdala–cortical function, prior to postnatal influences.

Method: Healthy pregnant women (N = 89) completed fetal resting-state functional magnetic resonance imaging (rsfMRI) scans between the late second trimester and birth. Women were primarily from low socioeconomic status households with relatively high CM. Mothers completed questionnaires prospectively evaluating prenatal psychosocial health and retrospectively evaluating trauma from their own childhood. Voxelwise functional connectivity was calculated from bilateral amygdala masks.

Results: Connectivity of the amygdala network was relatively higher to left frontal areas (prefrontal cortex and premotor) and relatively lower to right premotor area and brainstem areas in fetuses of mothers exposed to higher CM. These associations persisted after controlling for maternal socioeconomic status, maternal prenatal distress, measures of fetal motion, and gestational age at the time of scan and at birth.

Conclusion: Pregnant women's experiences of CM are associated with offspring brain development in utero. The strongest effects were found in the left hemisphere, potentially indicating lateralization of the effects of maternal CM on the fetal brain. This study suggests that the time frame of the Developmental Origins of Health and Disease research should be extended to exposures from mothers' childhood, and indicates that the intergenerational transmission of trauma may occur prior to birth.

Key words: brain; fetal; childhood maltreatment; maternal; intergenerational transmission

J Am Acad Child Adolesc Psychiatry 2023;∎(∎):∎-∎. 🥺

ncreasingly, neuropsychiatric disorders are considered neurodevelopmental in etiology,¹ with a range of environmental exposures, such as lead exposure in early life and non-contingent rearing, significantly contributing to altered brain-behavior trajectories and risk for psychopathology.²⁻⁵ Parental experiences from parents' own childhood have also been established as a risk factor for psychopathology in the next generation.⁶ Notably, effects of childhood maltreatment (CM) on the subsequent generation can be long ranging, with persistent depressive symptoms shown to extend into the fourth decade of life in the offspring of mothers with prior CM.⁷ The public health relevance of intergenerational transmission of CM is thus considerable, as there is potential for early interventions, preferably before conception, to ameliorate the negative psychiatric sequelae of CM for multiple generations.

The underlying mechanisms of intergenerational transmission are still largely unclear. One explanation is that exposure to CM may have a negative impact on subsequent parenting practices, which may place children at greater risk.⁸ Another possibility is that CM may have an enduring influence on maternal psychobiology, which may influence the perinatal and early-rearing environment into which a child is born.^{9,10} Developmental Origins of Health and Disease (DOHaD) research has demonstrated an even earlier time frame for significant environmental influence, namely, during the prenatal period. The DOHaD model suggests that intergenerational transmission of maternal CM effects may begin prior to birth through long-term alterations in materal—or paternal—biology affecting gestational biology and fetal brain development.^{9,10} In the DOHaD model, the fetus "adapts" to his or her environment with "programmed" changes in their biology aimed at ensuring survival. for such intergenerational transmission comes from animal studies showing increased oxidative stress indicators in oocyte milieu in obese or stressed females and epigenetic alterations in the sperm of male rodents exposed to early life stress.^{11,12}

Although human research on the DOHaD model for maternal CM on brain development of the fetus is still lacking, recent studies in newborns show interesting initial results. In novel imaging work, Moog et al.¹³ reported that 4-week old infants of mothers exposed to CM had a 6% reduction intracranial volume. In addition, Hendrix et al.¹⁴ found that newborns of mothers who reported higher emotional neglect during their own childhood had stronger fuctional connectivity between the amygdala and the ventomedial prefrontal cortex (vmPFC) and dorsal anterior cinculate cortex (dACC). This association was specific to emotional neglect and was not explained by maternal distress during pregnancy. More recently, Khoury et al.¹⁵ reported an association between maternal CM and lower brain volumes of overall gray matter and the amygdala over the first 2 years postpartum. The smaller amygdala volume was found only at older ages. Taken together, these studies provide initial evidence for altered brain development in infants of mothers who experienced CM in their childhood. By studying the infant brain proximal to birth, these studies minimized-but did not eliminate-potential influences of the postnatal environment. A more focused investigation of maternal CM effects on prenatal brain development is needed to provide evidence of the potential of prenatal programming in relation to maternal childhood maltreatment history.

A key brain region in the study of maltreatment exposure and altered neurodevelopment is the amygdala and its related brain network. Several studies of trauma-exposed youth report variation in amygdala based fear circuitry, mostly in the amygdala-prefrontal connection.^{16,17} Altered amygdala connectivity, in turn, was found to be associated with behavioral issues and mood disturbances.¹⁸ Furthermore, studies focusing on the effects of maternal CM on infant brain development either reported on amygdala functional connectivity¹⁴ or reported alterations in the volume of the amygdala.^{13,15} In line with the DOHaD model, these alterations of amygdala functional connectivity could be see as developmental adaptations in response to early adversity. In a seminal study by Gee et al.,¹⁹ for instance, children with a history of early adversity showed more mature amygdala-mPFC connectivity, which was associated with reduced anxiety symptoms (even though anxiety scores were still higher in the exposed children as compared to the non-exposed children). Together, these studies indicate that the amygdala and its connections are implicated in early adversity, in both the current and next

generations. In this report, we focus on amygdala-cortical functional connectivity as a target for the effects of intergenerational transmission of trauma prior to birth.

178 The current study aimed to examine the effects of 179 maternal CM on fetal amygdala-cortical functional con-180 nectivity in late pregnancy in a predominately low-181 resource, Black American sample. Given that the major-182 ity of studies examining CM recruit participants from 183 184 predominately White, highly educated, low-risk commu-185 nities, resulting in deficient representation of individuals 186 from low-resource and racial and ethnic minority groups, 187 we recruited from a low-resource, high-risk population. In 188 addition, rates of maltreatment are usually high in these 189 populations, providing a sample with a wider variety of 190 191 risk.²⁰ Because there are sex differences in fetal and child brain development,^{21,22} prenatal programming,²³ and rates 192 193 of neuropsychiatric disorders,²⁴ we examined sex as a 194 moderator of the influence of maternal CM on fetal 195 functional connectivity. All models controlled for maternal 196 distress during pregnancy to better isolate the influence of 197 198 maternal CM. 199

METHOD

Participants

204 A total of 221 pregnant women were recruited between the 205 18th and 36th gestational weeks into a longitudinal cohort 206 study based in . Only pregnant women >18 years of age, Q 207 native English speaking, with singleton pregnancy, were 208 eligible to participate. Only fetuses with normal fetal brain 209 210 anatomy, as assessed by ultrasound and magnetic resonance 211 imaging (MRI) examination, were included in the study. 212 Normal fetal brain anatomy was defined as having no 213 detected anomalies in the fetal brain by the referring 214 physician or the research team. Fetal gestational age (GA) 215 was checked by a referring physician using ultrasound ex-216 217 amination at the MRI visit. At age 3 years, scanned mothers 218 were invited for a child play visit at the laboratory, at which 219 point retrospective maternal childhood maltreatment his-220 tory information was obtained as part of a larger question-221 naire battery. 222

223 For the present analyses, we excluded cases with missing 224 maltreatment history data (n = 51). Fetal scans of low Q4225 image quality due to large artifacts (eg, air-tissue suscep-226 tibility) or excessive movement (n = 46) and scans with 227 different scanning parameters (n = 6). Other exclusionary 228 criteria were the presence of prenatal or birth complications 229 230 (ie, premature rupture of membranes, intrauterine growth 231 restriction, preeclampsia; n = 6), extreme preterm birth 232 (<34 weeks of pregnancy; n = 11), and extremely low 233 birthweight after controlling for gestational age (z scores 234

of +2 or -2; n = 4).²⁵ Finally, cases with too few artifactfree frames (<100) were excluded from the study (n = 5). These exclusions resulted in a final sample of 89 motherfetus dyads (34 female fetuses), mean fetal age (at scan) 32.55 weeks (SD = 4.14; range 20.57-39.57 weeks) for the analyses performed here. The resulting sample consisted of 42% of fetal cases in the original sample. This is a typical attrition rate, given the complexity of fetal scanning and a 3-year postnatal follow-up.²⁶

All study procedures were approved by the Human Investigation Committee of <censored>, and all women provided written informed consent prior to participation. Sociodemographic characteristics were collected via online questionnaires (Qualtrics) during the pregnancy functional MRI (fMRI) visit. This included information on drug use during pregnancy (smoke exposure and alcohol consumption), which was measured as part of a health questionnaire designed for this study. Birth outcome data were collected from medical records. Sociodemographic characteristics and birth outcomes of the included mother–fetus dyads (N = 89) are provided in Table 1.

Childhood Maltreatment and Psychosocial Health Measures

Maternal Maltreatment. Maternal exposure to CM was obtained using the Childhood Trauma Questionnaire (CTQ),²⁷ a 28-item self-report questionnaire that retrospectively assesses 5 types of childhood maltreatment: emotional, physical, and sexual abuse, and emotional and physical neglect. Each maltreatment type is assessed with 5 items measured on a 5-point Likert-type scale, with total scores for each subscale ranging from 5 to 25. The CTQ has excellent criterion-related validity (ie, internal consistency of $\alpha = 91$).²⁷ Mother completed the CTQ during the age 3 years laboratory visit, as part of a larger questionnaire battery.

Total CTQ score was computed by summing all subscale scores, with higher scores indicating greater CM severity. The total score was log-transformed to adjust for skewness. Analyses used continuous scores to mitigate data loss associated with data dichotomization. However, dichotomized CTQ scores were computed to characterize the prevalence of maltreatment in our sample. Following prior studies,¹³ dichotomized CTQ scores were based on suprathreshold exposure to at least 1 type of CM (CM+) compared to no or low exposure (CM–). CTQ thresholds for moderate to severe emotional, physical, and sexual abuse are ≥ 13 , ≥ 10 , and ≥ 8 , respectively. Thresholds for emotional and physical neglect are ≥ 15 and ≥ 10 .²⁷ Missing values were mean imputed only when no more than 1 item was missing per subscale. Maternal Prenatal and Postnatal Distress. Maternal negative affect and distress during pregnancy were measured 294 using 5 scales that assessed mood symptoms and indices of 295 296 stress: the Center for Epidemiological Studies Depression 297 Scale (CES-D),²⁸ the State Trait Anxiety Inventory (STAI; 298 only the state measures were collected, not trait),²⁹ the Penn 299 State Worry Questionnaire (PSWQ),³⁰ the 10-item 300 Perceived Stress Scale (PSS-10),³¹ and the Satisfaction Q 301 with Life Scale (SWLS).³² Each measure addresses different 302 303 categories of negative affectivity and stress in pregnant 304 women. To reduce the number of tests and to extract the 305 overlapping variance of these constructs, we combined these 306 measures using exploratory factor analysis, following prior 307 reports.^{26,33} The resulting single factor, hereafter referred to 308 as the Negative Affectivity and Stress Factor (NASF), was 309 310 used to quantify maternal prenatal distress and negative 311 affect. The NASF was standardized, meaning that scores of 312 0 indicate average distress, whereas positive scores indicated 313 stress higher than average and negative scores lower than 314 average. A graphical representation of our factor score, 315 316 including factor loadings, is presented in Figure S1, avail-317 able online. Postnatally, at the visit 3 years after birth, 318 mothers again completed measures of distress. Here, they 319 reported on anxiety (STAI) and depression (CES-D). 320

Maternal Health Practices During Pregnancy. Maternal 322 323 smoke and alcohol exposure during pregnancy were 324 measured using a self-report questionnaire about health 325 behaviors.³⁴ For smoking exposure, we examined both 326 smoking (self) and exposure to second-hand smoke. For 327 alcohol use, we computed a binary composite score based 328 329 on 4 questions about drinking alcohol during pregnancy 330 (eg, Have 5 or more alcoholic drinks per day (0 = no, 1 =331 yes); Limit my intake of alcohol (0 = no alcohol, 1 =332 alcohol); Drink alcohol until intoxicated (0 = no alcohol,333 1 =alcohol); Drink alcohol excessively (0 =no alcohol, 334 1 = alcohol)). Mothers scored a "0" when not drinking any 335 336 alcohol during pregnancy. For illustration purposes, we also 337 report frequencies for problematic alcohol consumption 338 during pregnancy (ie, Have 5 or more alcoholic drinks 339 per day). 340

MRI Data Acquisition

343 Fetal functional brain imaging was performed with a 344 Siemens Verio 70-cm open-bore 3-Tesla scanner with a 345 lightweight abdominal Siemens Flex Coil (Siemens, 346 Munich, Germany). Resting-state fMRI data were acquired 347 348 using a gradient echo planar imaging sequence: TR/TE 349 2000/30 milliseconds, flip angle 80°, 360 frames, axial 4-350 mm slice thickness, voxel size $3.4 \times 3.4 \times 4 \text{ mm}^3$, 351 repeated twice. Between 12 and 24 minutes of fetal 352

^aBaseline differences are assessed using t tests for continuous measures and χ^2 test for categorical measures.

resting-state fMRI data were collected per participant. The average system derived estimates for specific absorption rate was 0.22 watts per kilogram (SD = 0.06).

Resting-State fMRI Data Preprocessing

Functional MRI preprocessing followed previously published methodology.³⁵ Briefly, periods of fetal quiescence were manually identified using an FSL image viewer. Periods of low fetal motion were retained for analyses, resulting in exclusion of 37% of data and retention of an average of 173 frames, or 5.76 minutes (range = 103-344; SD = 53) per participant. Fetal brain masks corresponding to each epoch of low fetal motion were manually generated using Brainsuite.³⁶ Masks were used for segmentation, which was followed by reorientation, realignment, and normalization to a 32-week fetal brain template³⁷ using Statistical Parametric Mapping (SPM8) software implemented in MATLAB. Normalized images from each segment were then concatenated into one run, realigned, and smoothed with a 4-mm FWHM Gaussian kernel.

Functional Connectivity Analyses

The fetal bilateral amygdala region of interest (ROI) was defined by first manually tracing the left hemisphere amygdala of a 32-week fetal brain template³⁷ co-registered with the normalized fetal fMRI data. The left hemisphere trace was generated using the Multi-image Analysis GUI (MANGO; Research Imaging Institute, UT Health Science Center at San Antonio, TX; http://ric.uthscsa.edu/mango/) and added to a mirrored image in the contralateral hemisphere (see Figure S2, available online) to complete the ROI. The CONN functional connectivity toolbox $(v14n)^{38}$ was used to generate voxel-level bi-lateral amygdala resting state functional connectivity (RSFC) maps for each subject. CONN processing included linear detrending, nuisance regression using aCompCor of 5 principal components extracted from a 32-week fetal atlas white matter and CSF mask, 6 head motion parameters, and band-pass filtering at 0.008 to 0.09 Hz.

Next, 2 second-level analyses were performed in SPM12: (1) 1-sample t tests to map fetal amygdala neuro-circuitry, and (2) linear regression with maternal maltreat-ment severity as a predictor and gestational age at scan as a covariate. Resulting t maps were transformed into enhanced Z maps using probabilistic threshold free cluster enhance-ment (pTFCE).³⁹ pTFCE integrates cluster information to provide voxel-level statistical inference in a probabilistic manner based on the Bayes rule, increasing sensitivity while also providing appropriate control for false-positive results, and is a recommended, developmentally sensitive strategy for improving reliability in the context of multiple

comparisons.⁴⁰ Images were subsequently thresholded at p < .05 (uncorrected), k > 20. A more liberal threshold was used in comparison with adult fMRI analyses, because the the fetal brain is much smaller, resulting in much fewer voxels. The "effective resolution" is therefore smaller as compared to adult neuroimaging (for a discussion, see van den Heuvel and Thomason⁴¹). RSFC values were extracted from 2-mm radius spheres at the peak voxel of each cluster that survived correction, using the Response Exploration package for Matlab (REX),⁴² for subsequent analyses. If clusters had several peaks (ie, in larger clusters), we extracted spheres for all peaks.

Statistical Approach

604 RSFC values were extracted for ROIs that survived mul-605 tiple comparisons correction. Individual fetal connectivity 606 values were imported into SPSS (version 24.0.0.2, IBM 607 Corp.) to test potential factors contributing to observed 608 effects and to perform sensitivity analyses. First, we tested 609 610 whether the association between maternal CM severity and 611 fetal RSFC remained significant after controlling for 612 additional confounders. Based on prior studies, ^{13,14,43} we 613 selected maternal NASF, maternal age at scan, maternal 614 race, maternal education, family income, maternal smoke 615 616 exposure during pregnancy, and fetal sex as confounders. 617 Because very few mothers reported smoking (self) and 618 alcohol use during pregnancy, these were not taken into 619 account in the model. In addition, we controlled for 620 translational and rotational motion values and frame 621 622 count. It should be noted that fetal GA at scan was already 623 taken into account in the SPM analyses described above. 624 Because the fetal brain grows very rapidly, gestational age 625 is a very important confounder in our analyses. We 626 therefore partialled it out before making decisions 627 628 regarding which brain areas to extract for further analyses. 629 Second, the differential effect of CM by fetal sex on fetal 630 RSFC was tested by adding the interaction terms between 631 fetal sex and maternal CM to the model. All regressions 632 were run with 5,000 bootstrapped samples and a 633 p threshold of p = .05. 634

We also performed sensitivity analyses to address potential effects of outliers and fetal motion on our results. First, RSFC and CTQ values were identified by taking ± 3 SD as a cutoff. Tested models were refitted with outliers excluded and rerun. There was 1 outlier for the CTQ, with a very high score of 113 (greater than +3 SD above the mean). Furthermore, there was 1 outlier identified for left visual RSFC. Second, we re-ran our analyses using the dichotomized CTQ scores to see whether the effects remained constant. Third, we computed Pearson correlations between brain quality measures (translational and rotational movement and the frame count) and our 648 outcome variables to ensure that motion differences were 649 650 not confounding observed effects. Finally, we also checked 651 whether controlling for maternal postnatal stress at 3 years 652 postpartum altered the results, as childhood maltreatment 653 was reported by the mothers at the 3-year postpartum visit 654 and may be influenced by maternal current distress levels. 655 656 This was performed by rerunning our analyses with the 657 sum scores of the CESD (depression) and STAI (anxiety) 658 questionnaires added to our models. 659

RESULTS

Sample Description

664 As shown in Table 1, mothers had an average age of 25.2 665 years (SD = 4.55; range 18.2-37.1 years). Mean age of 666 fetuses was 32.6 weeks (SD = 4.1; range 21-40 weeks) GA 667 at the time of fetal fMRI measurement. Women's cumu-668 669 lative CTQ scores ranged from 25 to 113, and 43 women 670 (48.3%) reported exposure to at least 1 type of moderate-to-671 severe childhood maltreatment. We mean imputed 12 cases 672 (13.5%) because of missing values on 1 item. These cases 673 did not significantly differ on any predictors compared to 674 675 cases without missing data (CTQ scores: t = 0.561, p =676 .577; NASF scores: t = -0.188, p = .852). Two-sample t 677 tests and χ^2 tests showed that maternal maltreatment status 678 was not related to fetal age at scan, GA at birth, maternal 679 NASF scores, separate scores on the NASF questionnaires, 680 maternal depression at 3 years postpartum, motion values, 681 682 frame count, income, maternal education, or health status 683 (Table 1). However, mothers who reported CM vs those 684 who did not were on average younger (mean = 23.7 vs 26.5 685 years; t = 3.086, p = .003), and Black American women 686 were more likely than White women to be in the CM+ 687 group ($\chi^2 = 7.673$, p = 0.022). In addition, mothers in the 688 689 CM+ group reported higher anxiety levels at 3 years 690 postpartum as compared to the CM- group (t = -2.354, 691 p = .021). 692

Fetal Amygdala Neurocircuitry

695 Fetal amygdala connectivity (p < .001 and k > 20) is 696 displayed in Figure 1. Across the full sample, the fetal 697 amygdala network comprised strong positive connectivity to 698 ventromedial prefrontal cortext (vmPFC), cerebellum, 699 insula, and the medial and lateral temporal lobes. In 700 701 contrast, regions of the left superior frontal gyrus, left visual 702 association areas, left somatomotor cortex, and left pre-703 frontal contex (PFC) showed inverse patterns of connec-704 tivity. Positive connectivity was predominately bilateral, 705 706

Note: A one-sample t test highlights whole brain amygdala (bilateral) connectivity for the full sample (N = 89), controlling for gestational age at scan. Red coloring refers to positive connectivity, whereas blue coloring refers to inverse connectivity. Here, we see strong significantly positive connectivity between the amygdala and cerebellum, the insula, and the medial and lateral temporal lobes. We also note significantly inverse connectivity to the left superior frontal gyrus, left visual association areas, left somatomotor cortex, and left prefrontal cortex (PFC). Results are displayed on a 32-week gestational age cortical surface³⁷ at p < 0.001, k > 20.

whereas inverse connectivity was predominately localized in the left hemisphere. When examining fetal amygdala connectivity with a more liberal threshold (p > .05 and k >20), a similar pattern emerged (see Figure S3, available online).

Maternal CM and Fetal Amygdala Connectivity

CM severity was associated with altered connectivity in the amygdala network in several brain regions (Figure 2). Specifically, in fetuses of mothers with greater CM severity, we found relatively higher amygdala connectivity to the left prefrontal cortex (PFC) and left premotor area, as well as relatively less amygdala to brainstem, left visual cortex, and right premotor area connectivity. These

effects remained significant when controlling for maternal NASF, fetal sex, motion variables, frame count, maternal education, maternal income, and maternal age at scan as covariates. Table 2 (Steps 1 and 2) reports the results of the regression, and Figure 2 provides an overview of significant brain areas and scatterplots. Regression models are presented only with statistics for CM severity, fetal sex, and NASF; other covariates are not displayed because of space concerns. For a full model, including statistics for all covariates, see Tables S1.1 to S1.5, available online.

Sex Effects

Comparing male and female fetal amygdala connectivity in our 5 significant clusters, there were no significant sex differences (all p values >.05). The differential effect of CM on fetal brain connectivity by fetal sex [log(CTQ) by sex interaction] was only significant for the amygdala to the brainstem correlation (t = -2.109, p = .039). Simple slope analyses showed that the association between maternal CM on fetal amygdala to brainstem connectivity was marginally significant in female individuals (t = -1.803, p = .090) and was non-significant in male individuals (t = -0.908, p = .370), after controlling for confounders. Table 2 (Step 3) <<? provides the results of the regression model including the sex interaction.

Sensitivity Analyses

We first excluded 2 outliers (1 extreme CTQ score, 1 extreme RSFC score) and re-ran our models. This pro-duced similar findings, with 2 exceptions. First, the as-sociation between maternal CM and amygdala to left visual cortex connectivity became non-significant. Second, the sex interaction for the amygdala to the brainstem became non-significant. We then re-ran our models with dichotomized CTQ scores, which resulted in similar but weaker effects. Third, we found that maternal CM scores were not correlated with average translational (r = 0.112, p = .295) or rotational (r = 0.118, p = .269) motion or with frame count (r = 0.152, p = 0.155). Next, none of our RSFC values associated with motion or frame count (see Tables S1.1-S1.5, available online), suggesting that systematic differences in fMRI quality measures, which have the potential to confound stress-brain associations, are unlikely to explain the reported results. Finally, we checked whether controlling for maternal postnatal distress (anxiety and depression) affected our results. Fetal amygdala functional connectivity in all brain regions was still significantly associated with maternal CM (all p <.05), except for the brainstem region (t = -1.926, p = .059).

Journal of the American Academy of Child & Adolescent Psychiatry Volume ■ / Number ■ / ■ 2023

www.jaacap.org

Note: T-score contrast maps from regression analysis of log transformed maternal Childhood Trauma Questionnaire (CTQ) summary scores with whole brain amygdala connectivity are displayed on a 32-week gestational age cortical surface³⁷ in 3 dimensions (A) and on cortical slices (B). These images are pTFCE corrected p < 0.05 and k > 20. The lower panel (C) shows scatterplots including a linear regression line and distribution of each outcome, per brain area. We observed relatively more amygdala connectivity to left prefrontal cortex (PFC) and left premotor, right premotor and relatively less amygdala connectivity to brainstem, and left visual cortex. Results remained significant after deletion of 2 outliers, except for the amygdala to left visual result (became non-significant).

DISCUSSION

In this study, pregnant women's experiences of childhood maltreatment were reflected in offspring brain amygdala network connectivity in utero. Based on a sample of low-SES, predominantly Black American women, mothers' greater exposure to childhood maltreatment was associated with variation in fetal functional connectivity between the amygdala and key brain regions involved in emotion regulation networks and sensorimotor and perceptual processing. Sex differences were examined, and, contrary to some

reports on prenatal exposures and early brain develop-ment,^{23,44} they were absent. However, interactions may be underpowered because of our modest sample size. In addition, we report on general amygdala functional con-nectivity in utero, showing that the amygdala and prefrontal areas are already functionally connected in late gestation. Our findings add to prior work suggesting that women's adverse experiences from their own childhoods can alter their offspring's neurodevelopmental trajectories with im-plications for psychiatric disease risk,⁴⁵ yet, similar to a few

Note: all models are additionally controlled for maternal age at scan, maternal race, maternal education, family income, maternal smoke exposure during pregnancy, translational and rotational motion, and frame count in step 1 of each model. Select covariates are displayed in this table to enhance readability, but Tables S4.1 to S4.5, available online, display the association between all covariates with fetal amygdala brain connectivity. All models were run with 5,000 bootstrapped samples; b = unstandardized beta; CTQ = Childhood Trauma Questionnaire (total sum score); NASF = 014 Negative Affectivity and Stress Factor; PFC = prefrontal cortex; SE = standard error.

other reports,¹³⁻¹⁵ they isolate the timing of influence to biological processes active in the intrauterine or even preconception period.

Altered Fetal Amygdala FC Following Maternal Childhood Maltreatment

Overall, fetuses of mothers exposed to maternal childhood maltreatment manifest relatively more functional connectivity of the amygdala to the left prefrontal and premotor

1050 areas, and relatively less functional connectivity of the 1051 amygdala to the brainstem and the right premotor cortex. 1052 The extent of frontoamygdala effects extended over a large 1053 part, mostly medial, of the prefrontal and premotor area. 1054 This finding is consistent with Hendrix et al.,¹⁴ who also 1055 1056 reported stronger connectivity of the left amygdala and 1057 mPFC in newborns of mothers exposed to childhood 1058 maltreatment. Our study extends prior research by estab-1059 lishing that maternal childhood maltreatment may influence 1060

offspring's amygdala-PFC network development before birth. Taken together, our report and those of others show 1061 that the amygdala-PFC network may be altered starting in 1062 1063 the womb and that this alteration persists into infancy. 1064 Although the long-term functional significance of these 1065 neural alterations remains unclear, more positive coupling 1066 between the amygdala and dACC is associated with 1067 heightened threat sensitivity and anxiety disorders in chil-1068 1069 dren⁴⁶ and adults.⁴⁷ Future longitudinal work is required to 1070 determine whether altered frontoamygdala circuitry in utero 1071 is associated with similar behavioral outcomes. 1072

Interestingly, we observed lateralization of effects, with 1073 stronger effects of maternal childhood maltreatment expe-1074 1075 riences in the left hemisphere. Two other studies on the 1076 effect of maternal childhood maltreatment on newborn 1077 brain development also reported stronger effects for the left 1078 hemisphere compared to the right.^{13,14} In addition, we 1079 showed left lateralization of fetal amygdala functional con-1080 nectivity. Whether left lateralization of amygdala connec-1081 1082 tivity and lateralization of the effect of maternal CM are 1083 related is unclear. It could be that, because of its relative 1084 faster growth during fetal brain development, the left 1085 hemisphere is more vulnerable to prenatal exposures, such 1086 as changes in gestational biology related to maternal 1087 maltreatment history.⁴⁸ Several fetal MRI and sonography 1088 1089 studies have shown that left laterialization starts in utero, by 1090 identifying a larger left hemisphere and larger gray matter 1091 volumes on the left side.⁴⁸ Very recently, a fetal resting-state 1092 fMRI study demonstrated lateralization in the fetal con-1093 nectome, with left lateralization in the prefrontal cortex.⁴⁹ 1094 1095 Together with our results, these findings indicate that 1096 functional connectivity patterns may already lateralize dur-1097 ing prenatal brain development. 1098

1100 Potential Effect of Maternal Prenatal Distress

1101 Our study examined whether maternal psychological 1102 distress during pregnancy, including depressive symptoms, 1103 anxiety, worrying, and lower quality of life, affected the 1104 association between maternal childhood trauma and fetal 1105 amygdala connectivity as a confounder. Maternal psycho-1106 logical stress during pregnancy did not significantly 1107 1108 contribute to the model, and all effects of maternal CM 1109 remained significant when controlling for maternal psy-1110 chological distress during pregnancy. This seems to indicate 1111 dissociable impacts of childhood maltreatment that yield 1112 effects independent of prenatal distress. Our finding is in 1113 1114 line with previous reports on the effects of maternal CM on offspring brain volume^{13,15} and on newborn functional 1115 1116 connectivity,14 in which the effects of maternal CM also 1117 remained significant after controlling for maternal prenatal 1118 (psychological) distress. Notably, unlike Moog et al.¹³ and 1119

Hendrix *et al.*,¹⁴ we did not find higher maternal prental distress levels in women exposed to CM as compared to those without CM. This could potentially be due to the high levels of prenatal distress in *all* of the mothers in our high-risk sample. The women in our sample are predominantly single mothers, with a low income, with approximately 60% having an annual income below \$20,000.

Fetal Sex as Moderator

We did not find any interactions with fetal sex for the association between maternal CM and fetal amygdala function connectivity. However, with our modest sample size, interactions may be underpowered, and/or outlier influences can exert unintended effects. We emphasize that our results regarding fetal sex are preliminary and mainly intended to aid in hypothesis generation. Future investigation of sex differences in larger prenatal neuroimaging studies is certainly warranted.

Mechanisms of Intergenerational Transmission

1142 Several potential pathways by which mothers' childhood ex-1143 periences may affect the next generation prior to birth and 1144 independent of current distress have been suggested.^{9,10} First, 1145 CM-related epigenetic alterations in the maternal germline 1146 that survive re-establishment of post-conception epigenetic 1147 1148 alterations are a potential mechanism of transmission. CM-1149 related paternal epigenetic alterations are less well explored, 1150 but could also play an important role, given that women with 1151 high CM have a higher chance of pairing with CM-exposed 1152 men, based on the principles of "assortative pairing."⁵⁰ Sec-1153 1154 ond, CM may lead to changes in the maternal oocyte cyto-1155 plasm (such as to mitochondria) that in turn influence her 1156 developing embryo. Third, from a life course perspective, 1157 researchers have suggested that CM-associated changes in 1158 maternal gestational biology, such as atypical endocrine (often 1159 hypothalamic-pituitary-adrenal [HPA] axis) or immune-1160 1161 inflammatory regulation may shape fetal development.⁵¹ 1162 These changes are intrauterine perturbations that the 1163 fetal-placental unit "senses" and to which the fetus adapts, 1164 leading to alterations in anatomy and/or physiology such as 1165 decreased neurogenesis, variation in neuronal migration, and 1166 formation of synapses.⁵² In the emerging field of intergener-1167 1168 ational transmission, 1 report showed that maternal CM was 1169 associated with an almost 25% increase in placenta-derived 1170 maternal peripheral blood CRH levels with implications for Q8 1171 birth age, weight, and temperament,⁵³ and our group found 1172 that maternal CM was associated with a reduction in fetal 1173 heart rate variability, an index of less adaptive ANS develop-1174 1175 ment and relevant for future emotion regulation.⁵⁴ Finally, 1176 inherited psychiatric risk should not be excluded as a potential 1177 pathway, as parents with psychiatric illnesses are more likely to 1178

1099

maltreat their children.⁵⁵ Alterations in fetal functional connectivity may be (also) related to this inherited psychiatric risk. We do want to emphasize, however, that parents at psychiatric risk should not be stigmatized—the fact that a parent has a psychiatric illness does not mean that they will maltreat their child(ren).

1186 Amygdala Functional Connectivity In Utero

1185

1187 Across all fetuses, on average 32 weeks old, and controlling 1188 for gestational age at scan, there were robust findings of 1189 functional connectivity between the bilateral measurements 1190 of the amygdala and key brain regions. Specifically, we 1191 identified significantly positive connectivity between the 1192 amygdala and cerebellum, insula, and the medial and lateral 1193 1194 temporal lobes. We also found significantly inverse con-1195 nectivity to the left temporal junction, left superior frontal 1196 gyrus, left visual association areas, left somatomotor cortex, 1197 and left PFC. These connectivity patterns are consistent 1198 with other imaging studies showing the emerging con-1199 1200 nectome in neonates and preterm infants⁵⁶ and at 6 months 1201 postnatal.⁵¹ Data presented here show that, although 1202 immature and potentially weakly structurally connected, the 1203 amygdala and prefrontal areas are already functionally 1204 connected in late gestation. Notably, all inverse connectivity 1205 1206 reported in our study was left lateralized, indicating a po-1207 tential left lateralization of inverse amygdala functional 1208 connectivity in fetuses. Continued research is necessary to 1209 map the developmental trajectory of amygdala connectivity 1210 in early life, starting in utero. 1211

Potential limitations of the study warrant mention. First, 1212 1213 the present study did not use subject- specific anatomical 1214 regions of interest, as availability of reconstructed volumetric 1215 data for these cases is scarce. Consequenlty, potential indi-1216 vidual and age-related variation in amygdala structure is not 1217 captured in our approach. We expect that variation present 1218 1219 would have minimal influence on our approach, because the 1220 amygdala size paired with our functional image resolution 1221 (3.4 mm isotrophic) is not sensitive to individual anatomical 1222 differences. Second, the main predictor in our study, maternal 1223 childhood trauma, was collected using a retrospective ques-1224 tionnaire at child age 3 years. Retrospective accounts may 1225 1226 unduly reflect both recent events (eg, early parenting and/or 1227 birth experiences), and unresolved emotional trauma stem-1228 ming from childhood years. As such, retrospective measures of 1229 child maltreatment may carry additional information about 1230 resilience and/or later life experiences. It is a strength of our 1231 1232 study that the rates of childhood maltreatment in our sample 1233 are very similar to those in previous studies investigating the 1234 effect of maternal CM on the offspring's brain in similar 1235 samples (45% of mothers).¹⁴ Third, negative experiences in 1236 adolescence or adulthood, such as low social support, intimate 1237

partner violence, and stressful life events, may be more frequent in those mothers exposed to childhood maltreat-1238 ment.⁵⁷ These factors were not taken into account in the 1239 1240 current study, due to lack of power of the statistical analyses. 1241 Nevertheless, no differences were found between mothers 1242 with and without CM for education and family income, 1243 suggesting similar experiences in later life in both groups. 1244 Fifth, some concerns may be raised regarding the scales that 1245 the NASF is based on. Some items of the depression scale 1246 1247 (CES-D), for instance, may overlap with pregnancy symp-1248 toms, such as feeling tired and having trouble sleeping. 1249 Moreover, the trait scale of the State-Trait Anxiety Inventory 1250 and the Penn State Worry Questionnaire may measure 1251 maternal traits instead of distress during pregnancy. Future 1252 1253 research could utilize scales that are more commonly used in 1254 the perinatal period, such as the Edinson Postpartum 1255 Depression Scale (EPDS).⁵⁸ 1256

Another consideration regarding the present study is that our research concentrated on women from underrepresented racial and ethnic groups and women from low-socioeconomic households, raising questions about the generalizability of our results to other samples. It is important that groups less frequently engaged in research be intentionally recruited into studies to close extant gaps,⁵⁹ and there is scientific value in reducing SES variability when exploring topics of CM. In a final note, this study was conducted to test the falsifiable hypothesis that the fetal amygdala network would show altered connectivity in targeted regions, which raises the possibility that additional significant differences in fetal connectivity may be missed here. For instance, the cerebellum seems to be an important area for fetal functional connectivity according to two recent studies from our own group.^{26,35} In the future, there will be opportunity to use alternative approaches and to address additional questions in larger samples, as data from this project and others continue to be quality assured, processed, and released on an ongoing basis.

1280 Taken together, data presented here demonstrate that 1281 pregnant women's experiences of childhood maltreatment 1282 may be reflected their offspring's brain development in 1283 utero. Mothers' exposure to childhood maltreatment was 1284 1285 associated with variation in fetal functional connectivity 1286 between the amygdala and left prefrontal, left and right 1287 premotor areas, and the brainstem. In line with previous 1288 work, the largest effects of maternal CM were found in the 1289 left hemisphere, suggesting lateralization of CM exposure in 1290 the offspring's brain. No clear sex differences were found in 1291 1292 our study, but our modest sample size may not have been 1293 sufficient to detect (small) sex effects. Our findings add to 1294 prior work suggesting that women's adverse childhood 1295 experience can alter their offspring's neurodevelopmental 1296

trajectories before birth with implications for psychiatric 1297 disease, and extend the DOHaD model to include maternal 1298 childhood experiences. In particular, this study isolates the 1299 timing of influence to biological processes active in the in-1300 trauterine or pre-conception period. Our data support 1301 current changes in health policy moving toward collabora-1302 tive care models with a life course perspective in which 1303 assessment of childhood maltreatment and mental health 1304 1305 screening are routinely integrated into prenatal care-for 1306 women, and for their future children. 1307
